

Robust Environmental Mapping by Mobile Sensor Networks

Hyongju Park¹, Jinsun Liu², Matthew Johnson-Roberson³ and Ram Vasudevan¹

Abstract—Constructing a spatial map of environmental parameters is crucial step to prevent hazardous chemical leakage, forest fires, or to estimate the spatially distributed physical quantities, e.g., terrain elevation/radiation. Although previous methods can do such mapping tasks efficiently via dispatching a group of autonomous agents, the satisfactory convergence to the true distribution is guaranteed only when none of the robots/sensors/agents fail. A broad class of hardware and software failures are, however, commonly found in real-world applications, and will not only undermine overall mapping performance but could be critical to human safety as well. This paper presents a Bayesian approach for estimating an environmental parameters by deploying a group of mobile robots capable of ad-hoc communication equipped with short-range sensors. The topological (locations) and spatial properties (e.g., radiation level, magnetic field strength, temperature levels, etc), which constitute the target state are unknown and are characterized by a prior probability distribution over bounded domain. To this end, we present a general framework for coordinated multi-agent deployment aimed for good/better mapping performance even when some part of the sensors fail. First, for efficient robot-target assignment, we utilize the higher order Voronoi diagram where workspace is partitioned into disjoint regions and each region is associated with least one robots. Then, robots will be deployed to maximize the likelihood that at least one robot detects every target in their associated region. A suite of simulation results is presented to demonstrate the effectiveness and robustness of the proposed method compared to existing methods.

I. INTRODUCTION

A team of mobile robots equipped with ad-hoc communication and sensing devices, a *Mobile Sensor Network* (MSN), has a wide range of potential applications, including, exploration, surveillance, search and rescue missions, environmental monitoring for pollution detection and estimation, target tracking, cooperative detection of hazardous materials in contaminated environments, forest fire monitoring, oceanographic modeling, etc. [1]–[3] to name a few. This paper studies environmental mapping via MSNs where an autonomous fleet with limited sensing/processing capability, trying to estimate some unknown, spatially distributed target of interest given some *a priori* measurement. A few real-world application includes, building precipitation map, DEM, radiation map, heat distribution map, etc, via autonomous UAVs. Due to the advantages of utilizing large number of MSNs which is known to be relatively cheaper than other

robots, there are considerable efforts to achieve environmental mapping via MSNs, e.g., [4]–[8]. To best of our knowledge, there is little to no known method that is scalable to large number of sensors, that is capable of obtaining accurate representation map of a complex environment, e.g., terrain elevation, efficiently and rapidly, and that can provide robustness to sensor failures, e.g., erroneous sensor readings, as well. This paper aims to develop a class of cooperative detection model and deployment strategy, that enable for MSNs to autonomously and collectively obtain an accurate representation of an arbitrary environmental map efficiently, which has guaranteed robustness to a bounded number of sensors’ failures, under the Bayesian framework.

One of the most popular method of addressing the problem of Environmental mapping via deploying MSNs has been defining a mutual information function [9], and robots are controlled to follow the information gradient. [6] has studied the multi-agent environment mapping problem, where a mutual information gathering—utilize this idea of maximizing information gain—was used to control multiple robots to build a intensity map in a hazardous environment. Recently, [5] has proposed algorithm utilize the gradient of mutual information to enable MSNs to estimate a map of finite events in the environment while avoiding failures due to unknown hazards. They considered probabilistic robot failure model where probability of failure of each robot depends on the distances between hazard and the robot. They utilized the history of robot failures to avoid hazardous areas. In [10], the authors considered the problem of detecting a time-inhomogeneous Poisson process concealed in the background radiation using MSNs. As was noted previously [5], [7], the computational complexity for computing the *information gradient*, which is used as the key control policy is exponential of the number of robots, sensor measurements and environment discretization cells. However, in general the computation of the gradient requires that every robot be omniscient, i.e., to have current knowledge of every other robots position and sensor measurements, For the reason, in most cases, mutual information-based methods are limited to small groups of robots with fully connected network.

Also, there are studies which applied various relaxations techniques for the information gathering by robot teams to avoid the computational complexity. In [7] proposed a fully decentralized approach where the gradient of mutual information was used to drive a network of robots for general environmental mapping tasks. They used sampling technique to reduce the size of the belief matrix for better computational efficiency. At least from the current stand, their approach has not been shown to be able to do mapping

of a general complex environment, which is of our problem of interest. Their experimental results presents the case of robot fleets are inferring finite number of cell environment. In [11], employed particle filters for approximating mutual information which enable them to use nonlinear and non-Gaussian target state and sensor models. Their methods are shown to localize a target efficiently via MSNs which maximize their information gain at each step, to name a few. We note that all these works still assume existence of a centralized fusion center to collect the information from multiple sensors and to make a global decision.

It is worth mentioning the work of Lynch et al. [8], who devise distributed control law for MSNs to decrease the variance of their state estimate of the environment model where they utilized Average Consensus filter to propagate information among the robots. Their presented approach is scalable to large number of agents, fully decentralized, and should work under switching network topology as well as long as the network is connected; however their approach mainly focuses on information diffusion technique via communication among robots, and does not utilize the spatially distributed nature of the MSNs. If configured properly¹, MSNs are expected to handle large region environmental mapping task efficiently while maintaining minimal overlapping sensing regions.

In this paper, we present a class of computationally efficient, scalable, decentralized deployment strategies that are robust to sensor failures. We employ classical higher order Voronoi tessellation [12] to achieve spatially distributed allocation of MSNs for efficient environmental mapping task. We formulate our cost function based on a particular tessellation, and use gradient descent of the cost as our decentralized deployment strategy for MSNs. By doing so, each robot can compute gradient using merely local informations without the necessity of communicating with central server. Thus, in our paper, the central entity is only required to fuse and update the information gathered from MSNs, but not to generate control policies for robots, which is often the case for mutual information gathering approach [5], [7]. Furthermore, our paper also employed particle filter along with low discrepancy sampling method for the purpose of approximating the belief of the complex, continuously distributed target efficiently, and rapidly.

Also, we present a novel combined sensor model to assign different weights to robots given a targets by taking into account the spatial relationship between robots and the target state. We derive our detection model bases on a classical binary model [13], [14] that depends on the configuration of robots. To connect the detection model to the measurement model we rely on a nonrestrictive assumption that if a robot fails to discern target from others; it may not provide the correct sensor reading for the target. This type of assumption is not new. [15] has adopted similar combined sensor model which has been experimentally verified with the laser range

finder and a panoramic camera measurement. Our proposed sensor model enable us to decouple the information state from the detection tasks, such that computing the gradient is computationally sound whose complexity has turned out to be linear with respect to the number of sensors.

We provide robustness to our method by adopting higher order Voronoi tessellation [12] where each region from a partition is assigned to multiple robots and such redundant assignment will provide robustness to sensor failures. To best of our knowledge, almost all studies about environmental mapping by MSNs up to date have not take into account such adversarial scenarios, nor presented performance guarantee by showing convergence to ground truth value, either by analysis or by numerical simulation in the case when some part of the sensors will fail, become malicious or compromised. One exception is [5], who considered probabilistic robot failure model where probability of failure of each robot depends on the distances between hazard and the robot. They utilized the history of robot failures to avoid hazardous areas. The use of mutual information gradient implies that the method could potentially be robust to sensor failures. In our paper, we consider a broader class of sensor failure scenarios than that considered in [5]. In our study, we relaxed their assumption that robot failure should depends on the location of hazards, but it can happen due to many other reasons (e.g., malicious robots, battery depletion, etc). [6] use the ordinary Voronoi tessellation for robot-target assignment. Al though these ordinary Voronoi-based approaches are considered to be the most efficient under ideal cases, such performance is not guaranteed even in the case of single sensor failure [16].

The main contributions of this paper are as follows: We propose a scalable, spatially distributed, computationally efficient, decentralized controller for MSNs which can perform environmental mapping task rapidly without a help of central entity. We present a novel sensor model, to remove the computational burden of maintaining mutual information by MSNs by decoupling information gathering and detection, while maintaining a satisfactory mapping performance. We adopted higher order Voronoi tessellation for optimal robots-target assignment, in order to provide robustness under general class of sensor failures whose number is bounded. All of which has been extensively validated via a suite of numerical simulations.

Organizations: The rest of the paper is organized as follows. Section II presents notation used in the remainder of the paper, formally defines the problem of interest, and reviews a recursive Bayesian filter tailored to the problem. Section III presents our combined probabilistic sensor model. The deployment strategy is formally presented in Section IV. Section V discusses an approximate belief update method via particle filters. The robustness of our deployment and effectiveness of the belief update approach is evaluated via numerical simulations in Sections VI. Finally, Section VII concludes the paper and proposes a number of future directions.

¹One popular example of this is the work of [2] where centroidal Voronoi configuration of MSNs are proven to achieves optimal coverage.

II. PROBLEM DESCRIPTION

This section presents the notation used throughout the paper, an illustrative example, and the problem of interest.

A. Notations and Our System Definition

Throughout the text, the italic bold font is used to describe random quantities, a subscript t indicates that the value is measured at time step t , and $\mathbb{Z}_{\geq 0}$ denotes nonnegative integers. Given a continuous random variable x , if it is distributed according to a Probability Density Function (PDF), we denote it by f_x . Given a discrete random variable y , if it is distributed according to a Probability Mass Function (PMF), we denote it by p_y . Consider a group of m mobile robots deployed in a workspace, i.e., ambient space, $\mathcal{Q} \subseteq \mathbb{R}^d$ where $d = 2, 3$. This paper assumes $d = 2$ though the presented framework generalizes to $d = 3$. Let $\mathbb{S}^{d-1} = \{s \in \mathbb{R}^d \mid \|s\| = 1\}$ be a unit circle/sphere, then the state of m robots is the set of locations and orientations at time t , and it is represented as an m -tuple $x_t = (x_t^1, \dots, x_t^m)$, where $x_t^i \in \mathcal{Q} \times \mathbb{S}^{d-1}$. The state of robots are assumed completely known. We denote by the set $x_{0:t} := \{x_0, \dots, x_t\}$ the robot states up to time t .

The group of robots follow a way-point-based, discretized, deterministic kinematic motion model:

$$x_{t+1} = x_t + u_t, \quad t \in \mathbb{Z}_{\geq 0} \quad (1)$$

where $u_t \in \mathcal{U} \subseteq \mathbb{R}^d$ is the control. Similarly, let $u_{0:t}$ be the sequence of control policies up to time t . We define a *target* to be a physical object or some measurable quantity spatially distributed over a bounded domain. Let z be the *target state* which is a random vector. The target state consists of location, $q \in \mathcal{Q}$, and information state (i.e., quantitative information about the target), $\mathcal{I} \in \mathcal{I} \subseteq \mathbb{R}$ where we let $\mathcal{I} = [I_{\min} I_{\max}]$. The Cartesian product $\mathcal{Z} = \mathcal{Q} \times \mathcal{I}$ is the *target state space*. Let $y_t = (y_t^1, \dots, y_t^m)$ be binary random m -tuple which indicates the observation made by m robots at time step t where $y_t^i \in \{0, 1\}$ for each i . Let the set $y_{1:t} := \{y_1, \dots, y_t\}$ denote observations made by robots up to time t . Let y_D a binary random tuple of size m where each $y_D^i \in \{0, 1\}$ which denotes the detection by i th robot. Finally, we let $\mathcal{F} \subseteq \{1, \dots, m\}$ be the index set of robots whose sensors have failed.

Example 2.1 (Airborne LiDARs for DEM generation):

Consider a group of autonomous aerial vehicles trying to acquire an accurate Digital Elevation Model (DEM)² of some bounded region using airborne LIDAR measurements. The first problem is: given a finite number of vehicles, how to deploy those vehicles such that the probability that robots will fail to targets dispersed over the region of interest stays minimum. Also, it may be possible that LIDAR measurements from a part of the fleet are corrupt or unreliable which can potentially degrade the quality of DEM. Taking such adversarial scenarios into account, it is crucial to design a deployment strategy along with an

underlying sensor model, which can guarantee worst-case optimal target detection performance. Finally, it is also important to process the measurement to update the belief on target state over time in efficient manner such that, within a reasonable time, the autonomous fleet can obtain an accurate DEM model.

B. Deployment strategy for the worst-case optimal target detection under sensor failures

For a given target located at $q \in \mathcal{Q}$, let $p(y_D^i = 0 \mid x^i, q = q)$ be the probability that i th robot fails to detect target located at q , and $y_D^i = 1$ otherwise. In a similar manner, $p(y_D = \mathbf{0} \mid x, q = q)$ is the probability of a joint event that a group of m robots fail to detect the target at q . For the case when sensors with identifies \mathcal{F} have failed, our aim is to find an optimal configuration which solves:

$$x^* = \arg \min_{x \in \mathcal{Q}^m} p(y_D = \mathbf{0} \mid x) \quad (2)$$

subject to

$$p(y_D = \mathbf{0} \mid x, q = q, \mathcal{F}) < 1, \quad q \in \mathcal{Q}. \quad (3)$$

In other words given the sensor failure \mathcal{F} , for each target, there must be at least one robot that can detect it, which is an essential constraint for the environmental mapping task³. The target distribution of q has been marginalized out. Unfortunately, obtaining the global solution of even the outer minimization problem can be proven to be NP-Hard by reduction from a simpler static locational optimization problem, namely, *m-median problem*⁴. To overcome the computational complexity, we will consider a gradient descent (greedy) approach where control policy at each time step minimizes the missed-detection probability of targets by robots at their future locations (one-step lookahead). We will utilize the higher order Voronoi tessellation [12] for robot target assignment, and will show that the solution under such assignment solves (2).

C. Combined sensor model

Here, we make a simple assumption that given a target, a sensor can correctly measure the target only if the sensor can detect target (i.e., the sensor can discern the target from others.) *a priori*. We further assume that, if a sensor can detect a target, a measurement of the target by the sensor is simply corrupted by noise (e.g., Gaussian). On the other hand, if a robot fail to detect a target, the measurement given the target may be unreliable and should not be considered equally as a correct measurement. These assumptions have turned out to be non-restrictive according to the work of [15] in which authors has experimentally verified a similar combined sensor model on a mobile robot using laser range finder and a panoramic camera measurement.

³This paper considers an average-case optimal solution with respect to sensor failures. For our purpose, the worst-case optimal (minimax) solution can, in fact, be too conservative.

⁴*m*-median problem is one of the popular locational optimization problem where the objective is to locate m facilities to minimize the distance between demands and the facilities given uniform prior. The problem is NP-Hard in general graph (not necessarily a tree).

²A digital elevation model (DEM) is a digital 3D model of a terrain's surface created from terrain elevation data.

D. Evaluation of mapping performance

We derive particle filter to recursively update approximate beliefs on a particular unknown environment. Let \hat{b}_t represent a the approximate posterior probability distribution of the target state at time $t \in \mathbb{Z}_{\geq 0}$, the initial belief \hat{b}_0 is assumed to be uniform density if no prior information on the target is available, and let \hat{b}^* be the PMF estimate of the *true posterior belief*⁵. To this end, we quantify the difference between the true posterior belief, b^* and our method via the Kullback-Leibler (K-L) divergence. We demonstrate via a suite of numerical simulations in Section VI that for a given $\epsilon > 0$ and $\mathcal{F} \neq \emptyset$, there is reasonably small $T > 0$ such that if robots use the proposed deployment strategy, $t > T$ implies $D_{\text{KL}}(\hat{b}_t || \hat{b}^*) < \epsilon$.

III. PROBABILISTIC RANGE-LIMITED SENSOR MODEL

In this section, we present our combined sensor model. Each mobile robot is equipped with a *range-limited sensor* that can measure quantitative information from afar and a *radio* to communicate with other nodes to share its belief. Each range sensor measurement of a target is corrupted by noise, and the measurement is valid only if the target has been detected. This combined sensor model joins the generic noisy sensor model with the binary detection model [13], [14]. In fact, this combined sensor model has been experimentally validated during an object mapping and detection task using a laser scanner [15]. We postulate that this model is general enough to model other range-limited sensors as well; as long as the sensor is capable of distinguishing the target from the environment, and has uniform sensing range. A few example sensors satisfying these characteristics are 360-degree camera, wireless antenna, Gaussmeter, heat sensor, olfactory receptor, etc. While performing the detection task, we assume each sensor returns a 1 if a target is detected or 0 otherwise. The ability to detect a target for each i^{th} robot is a binary random variable \mathbf{y}_D^i with a distribution that depends on the relative distance between the target and robot. This binary detection model, however, does not account for false positive or negatives. For example, the probability of the event that all m sensors with configuration x_t fail to detect the target located at $q \in \mathcal{Q}$ is:

$$\begin{aligned} p_{\mathbf{y}_D, t | x_t, \mathbf{z}}(\mathbf{y}_D, t = \mathbf{0} | x_t, \mathbf{z} = (q, I)) \\ = \prod_{i=1}^m p_{\mathbf{y}_D^i, t | x_t, \mathbf{q}}(\mathbf{y}_D^i, t = 0 | x_t, \mathbf{q} = q), \end{aligned}$$

where $\mathbf{0}$ is a m -tuple of zeros. For measuring a quantity of interest from a given environment, we consider a generic, noisy sensor model, where each sensor reports binary output given a target state consists of information and location. The likelihood function at time t is:

$$p(\mathbf{y}_t = \mathbf{1} | x_t, \mathbf{z} = (q, I)), \quad (4)$$

⁵We assume for now that the true posterior target distribution can be obtained, e.g., via exhaustive search and measurements made by a MSN on the target state.

which is the probability that i^{th} robot measured the target with intensity value of I at location q , i.e., positive measurement. A general example of the likelihood function is a Gaussian, $\omega \mathcal{N}(I, I^*, \sigma_I^2)$ where I^* the ground truth intensity value at q , σ_I^2 is the variance of the intensity at the target located at q , and ω is a normalization constant. Note that since the observations made by m robots are independent,

$$p(\mathbf{y}_t = \mathbf{1} | x_t, \mathbf{z} = (q, I)) = \prod_{i=1}^m p(\mathbf{y}_t^i = 1 | x_t, \mathbf{z} = (q, I)),$$

or (4) can be obtained via other distributed sensor fusion techniques (see e.g., [17]). In our sensor model, we assume that the random vector \mathbf{y} depends on \mathbf{y}_D which is a random m -tuple corresponds to detection by m robots such that $\mathbf{y}_D = (\mathbf{y}_D^1, \dots, \mathbf{y}_D^m)$ where $\mathbf{y}_D^i \in \{0, 1\}$ for all i when conditioned on x_t, \mathbf{z} , so that the conditional PDF can be computed as:

$$\begin{aligned} f_{\mathbf{y}_t | \mathbf{z}, x_t}(\mathbf{y}_t = \mathbf{1} | \mathbf{z}, x_t) \\ = f_{\mathbf{y}_t | \mathbf{z}, x_t, \mathbf{y}_D, t}(\mathbf{y}_t = \mathbf{1} | \mathbf{z}, x_t, \mathbf{y}_D, t \neq \mathbf{0}) \\ \times p_{\mathbf{y}_D, t | \mathbf{z}, x_t}(\mathbf{y}_D, t \neq \mathbf{0} | \mathbf{z}, x_t) \\ + f_{\mathbf{y}_t | \mathbf{z}, x_t, \mathbf{y}_D, t}(\mathbf{y}_t = \mathbf{1} | \mathbf{z}, x_t, \mathbf{y}_D, t = \mathbf{0}) \\ \times p_{\mathbf{y}_D, t | \mathbf{z}, x_t}(\mathbf{y}_D, t = \mathbf{0} | \mathbf{z}, x_t), \end{aligned}$$

where $\mathbf{y}_D \neq \mathbf{0}$ means there is $j \in \{1, \dots, m\}$ such that $\mathbf{y}_D^j = 1$ and $\mathbf{y}_D = \mathbf{0}$ means $\mathbf{y}_D^j = 0$ for all $j \in \{1, \dots, m\}$. If target is missed-detected, i.e., $\mathbf{y}_D, t = \mathbf{0}$, the measurement is taken as random and the likelihood function is modeled by uniform distribution, i.e.,

$$\begin{aligned} f_{\mathbf{y}_t | \mathbf{z}, x_t, \mathbf{y}_D, t}(\mathbf{y}_t = \mathbf{1} | \mathbf{z}, x_t, \mathbf{y}_D, t = \mathbf{0}) \\ = f_{\mathbf{y}_t | \mathbf{z}, x_t, \mathbf{y}_D, t}(\mathbf{y}_t = \mathbf{1} | \mathbf{z}, x_t, \mathbf{y}_D, t = \mathbf{0}) = I_{\text{range}}^{-1} \end{aligned}$$

where $I_{\text{range}} := I_{\text{max}} - I_{\text{min}}$. By the law of total probability,

$$\begin{aligned} f_{\mathbf{y}_t | \mathbf{z}, x_t}(\mathbf{y}_t = \mathbf{1} | \mathbf{z}, x_t) \\ = (1 - \underbrace{p_{\mathbf{y}_D, t | \mathbf{z}, x_t}(\mathbf{y}_D, t = \mathbf{0} | \mathbf{z}, x_t)}_{(*) \text{ the probability of missed detection}}) \\ \times \underbrace{f_{\mathbf{y}_t | \mathbf{z}, x_t, \mathbf{y}_D, t}(\mathbf{y}_t | \mathbf{z}, x_t, \mathbf{y}_D, t \neq \mathbf{0})}_{\text{the likelihood of reliable measurements}} \\ + I_{\text{range}}^{-1} p_{\mathbf{y}_D, t | \mathbf{z}, x_t}(\mathbf{y}_D, t = \mathbf{0} | \mathbf{z}, x_t). \end{aligned}$$

For the given target $\mathbf{z} \in \mathcal{Z}$, by minimizing $(*)$, one can ensure that the reliable measurements on the target state has been given more weight than the unreliable ones.

IV. DEPLOYMENT STRATEGY

This section presents a class of deployment strategies for target detection capable of providing relative robustness. At each time, m robots move to new locations so as to minimize the missed-detection probability to promote the next observations. Since the set of robots with faulty sensors is unknown, we chose not to pose our problem to deal with the worst-case sensor failure scenarios which could be too conservative (e.g., the probability that multiple sensors fail at the same time is low). Instead, we adopt a provably optimal robot-target assignment method which can ensure

that every target will be detected by at least one robot. This so called partitioned-based deployment is common to multi-robot coverage problems [2], [16], [18], [19]. The most popular one is based on the Voronoi tessellations (see e.g., [2], which we call a *non-robust deployment*). There are, in fact more general methods, which partition the workspace into l regions and assign $k \in \{1, \dots, m\}$ robots each region (note that if $k = m$, the method becomes *centralized*) [16]. By doing so, one can ensure that each target has a chance to be detected by at least one of the k sensors. This approach, which we call the *robust deployment*, can provide relative robustness by varying the value of k from 1 to m .

A. The higher-order Voronoi Partition for Robust deployment

We will utilize the higher order Voronoi Tessellation to achieve robust robot–target assignment. Given the maximum possible number of sensor failures, let's say $f = |\mathcal{F}|$, as noted before, we want to ensure that at least one robot can detect a target. One way to do so is using k -coverage method [20], where each target is being covered by at least k sensors. Also, we may use the higher order Voronoi tessellation, which, for a given number of sensors (generators), assigned exactly k number of sensors for every region from a partition. For both approaches if $k \geq f + 1$, the constraint is always satisfied. Since we have bounded sensors available, the second approach is more desirable, and we will present the method in this study. Consider m sensors and a workspace partition of \mathcal{Q} into l disjoint regions, W such that $W = (W^1, \dots, W^l)$, where $\cup_i W^i = \mathcal{Q}$, and $W^i \cap W^j = \emptyset$ for all i, j pairs with $i \neq j$. Suppose the target location is a random variable z with PDF $\phi : \mathcal{Q} \rightarrow \mathbb{R}_{\geq 0}$. For a given target $q \in \mathcal{Q}$, we define the probability that a sensor located at x can detect target, by using a real-valued function $h(\|q - x^i\|)$ as a probability measure⁶, which is assumed to decrease monotonically as a function of the distance between the target and the i^{th} sensor. Consider a bijection kG that maps a region to a set of k -points where the pre-superscript k explicitly states that the region is mapped to exactly k points. Additionally we make the following definitions:

Definition 4.1 (An Order- k Voronoi Partition [12]): Let x be a set of m distinct points in $\mathcal{Q} \subseteq \mathbb{R}^d$. The *order- k Voronoi partition of \mathcal{Q} based on x* , namely kV , is the collection of regions that partitions \mathcal{Q} where each region is associated with the k nearest points in x .

We also define another bijection ${}^kG^*$ that maps a region to a set of k nearest points (out of x) to the region. The total probability that all m sensors fail to detect a target drawn by a distribution ϕ from \mathcal{Q} is:

$$\int_{\mathcal{Q}} p_{\mathbf{y}_D | x, \mathbf{q}}(\mathbf{y}_D = \mathbf{0} \mid x, \mathbf{q} = q) \phi(q) dq. \quad (5)$$

⁶For the numerical simulations purpose, we further assume that $h(\cdot)$ is continuously differentiable function non-increasing on its domain, and the image of h must be in $[0, 1]$ for it to be a probability measure.

By substituting \mathcal{Q} with the workspace partition W , and $p_{\mathbf{y}_D | x, \mathbf{q}}(\mathbf{y}_D = \mathbf{0} \mid x, \mathbf{q} = q)$ with h , we have

$$H(x, W, {}^kG) = \sum_{j=1}^l \int_{W^j} \left(\prod_{x^i \in {}^kG(W^j)} (1 - h(\|q - x^i\|)) \right) \phi(q) dq \quad (6)$$

where we note again that the joint missed-detection events are conditionally independent, if conditioned on x . In fact, the order- k Voronoi tessellation is the optimal workspace partition which minimizes H for each choice of x and k :

Theorem 4.1 ([19]): For a given x and k , $H(x, {}^kV, {}^kG^*) \leq H(x, W, {}^kG)$ for all $W, {}^kG$.

Note that the order- k Voronoi partition V_k , along with the map G_k^* are uniquely determined given x , ϕ , and \mathcal{Q} .

Our proposed sensor model utilizes the deterministic workspace partitioning method based on the order- k Voronoi partition toward the probabilistic sensor model presented in Section III. In addition, we introduce additional hard constraint for the model, namely the *effective sensing range*, $r_{\text{eff}} > 0$, to take into account the fact that each sensor has its own maximum sensing range. For a given k , and the target $z = (q, I)$, our range-limited binary detection model is:

$$p_{\mathbf{y}_{D,t} | q, x_t}(\mathbf{y}_{D,t} = 1 \mid x_t, \mathbf{q} = q) = \begin{cases} h(\|q - x_t^i\|) & \text{if } q \in {}^kG_t^*(x_t^i) \cap \mathcal{B}(x_t^i, r_{\text{eff}}), \\ 0, & \text{otherwise,} \end{cases}$$

where $\mathcal{B}(x, r)$ is an open ball with radius r centered at x .

B. Gradient algorithm

This section will present gradient-decent-based deployment strategy. Given the current configurations, robots compute and move their next way-points, and the posterior belief is updated at the new locations given the information collected from their sensors. By using f_q , and (6), for a given x_{t-1} at time $t-1$, we want to obtain the next way-point x_t^* which solves

$$x_t^* \leftarrow \arg \min_{x_t} \left\{ \mathcal{L}(x_t) := \sum_{j=1}^l \int_{W_t^j} \prod_{x_t^i \in {}^kG^*(W_t^j)} (1 - h(\|q - x_t^i\|)) f_q(q) dq \right\}. \quad (7)$$

Note that for a given k , by substituting f_q with ϕ and x with x_t , (7) takes the identical form as $H(x, W, {}^kG)$ which was previously defined in (6). If h is differentiable, our deployment strategy can use the gradient $\nabla \mathcal{L}(x_t) = \left[\frac{\partial \mathcal{L}(x_t)}{\partial x_t^1}, \dots, \frac{\partial \mathcal{L}(x_t)}{\partial x_t^m} \right]$ where for each i ,

$$\begin{aligned} \frac{\partial \mathcal{L}(x_t)}{\partial x_t^i} = & - \sum_{\substack{j \in \{1, \dots, l\}: \\ W_t^j \in {}^kG^{*-1}(x_t^i)}} \int_{W_t^j} \frac{\partial h(\|q - x_t^i\|)}{\partial x_t^i} \\ & \times \prod_{\substack{l \in \{1, \dots, m\}: \\ x_t^l \in {}^kG^*(W_t^j), l \neq i}} (1 - h(\|q - x_t^l\|)) f_q(q) dq, \end{aligned}$$

to find the desirable control policy of the robots as described in Algorithm 1. Algorithm 1 uses coordinate gradient descent in cyclic fashion to obtain a sub-optimal solution, namely, \hat{u}_t for each time t . Algorithm 1 can be shown to be convergent

Algorithm 1: Gradient Algorithm

Input: $\mathcal{L}_k, \hat{x}_t, \epsilon > 0$
Output: \hat{u}_t
 $k \leftarrow 0, \Delta \leftarrow \epsilon$
while $\Delta > \epsilon$ **do**
 foreach $i \in \{1, \dots, m\}$ **do**
 $x_{t,k+1}^i \leftarrow x_{t,k}^i - \alpha_{t,k}^i \nabla_i \mathcal{L}_k(x_{t,k})$
 // $\alpha_{t,k}^i$ is a step-size obtained using a line search method
 $\Delta \leftarrow \mathcal{L}_k(x_{t,k}) - \mathcal{L}_k(x_{t,k+1})$
 $k \leftarrow k + 1$
 $\hat{x}_t^* \leftarrow x_{t,k}, \hat{u}_t \leftarrow \hat{x}_t^* - \hat{x}_t$
return \hat{u}_t

via Invariance Principle. The theorem along with the formal proof is contained in our previous paper [19].

V. IMPLEMENTATION: ENVIRONMENTAL MAPPING

In this section, we first introduce Bayesian filtering equations for our particular target distribution, and then present a particle filter to reduce the complexity of the map construction process.

A. Recursive Bayesian Filter

We present a brief overview of the Bayesian filter, and the derivation of the filtering equations for our primary goal: environmental mapping by m robots. Recall that $b_t(z)$ represent a *belief* on target state—the posterior probability distribution of the target state described by a random vector $z \in \mathcal{Z}$ —at time $t \in \mathbb{Z}_{\geq 0}$. In a similar manner, the belief of target information state I given the target located at q is given by:

$$b_t(I \mid \mathbf{q} = q) = f_{I|b_0, x_{0:t}, y_{1:t}, \mathbf{q}}(I \mid b_0, x_{0:t}, y_{1:t}, \mathbf{q} = q) \quad (8)$$

where we denote the initial belief on target state by b_0 . The belief on the complete target state z is:

$$b_t(z) = f_{z|b_0, x_{0:t}, y_{1:t}}(z \mid b_0, x_{0:t}, y_{1:t}) = b_t(I \mid \mathbf{q} = q) f_{\mathbf{q}}(q). \quad (9)$$

In our problem, the observation \mathbf{y}_t is conditionally independent of b_0 , $\mathbf{y}_{1:t-1}$, and $x_{0:t-2}$ when it is conditioned on z and x_t . Applying *Bayes' Theorem*, (8) becomes:

$$b_t(I \mid \mathbf{q} = q) = \eta_t f_{\mathbf{y}_t|z, x_t}(\mathbf{y}_t = \mathbf{1} \mid z = (I, q), x_t) b_{t-1}(I \mid \mathbf{q} = q) \quad (10)$$

where $\eta_t := (f_{\mathbf{y}_t|q, b_0, x_t}(\mathbf{y}_t = \mathbf{1} \mid \mathbf{q} = q, b_0, x_t))^{-1}$ is a *normalization constant*. By joining the (9) and (10), one can obtain a simplified form of the filtering equation:

$$\begin{aligned} b_t(z) &= \eta_t f_{\mathbf{y}_t|z, x_t}(\mathbf{y}_t = \mathbf{1} \mid z, x_t) b_{t-1}(z) \\ &= \left(\prod_{i=1}^t \eta_i f_{\mathbf{y}_i|z, x_i}(\mathbf{y}_i = \mathbf{1} \mid z, x_i) \right) b_0(z). \end{aligned}$$

B. Belief Approximation via SIR Particle Filter

For our numerical simulations, we consider a low discrepancy sampling method, namely, Halton-Hammersley sequence, to sample continuously distributed targets in $z \in \mathcal{Z}$. This approach has been used for sampling-based algorithms for robot motion planning [21]. We consider Sequential Importance Resampling (SIR) [22] for the particle filtering process. For a given distribution on target locations, $f_{\mathbf{q}}(q)$, at each time t , based on the observations, the locations belief hypothesis is populated for N_1 samples initially generated with Halton-Hammersley sequence, q^1, \dots, q^{N_1} where for each $i \in \{1, \dots, N_1\}$, $j \in \{1, \dots, N_2\}$,

$$\tilde{w}_t^{ij} \propto f_{\mathbf{y}_t|z_t, x_t}(\mathbf{y}_t = \mathbf{1} \mid \hat{x}_t, z = (q^i, I^{ij})).$$

In a similar manner, for each sample q^i the information belief hypothesis is populated for N_2 samples from \mathcal{I} initially generated by the Halton-Hammersley sequence. If we let $z_t^{ij} := (q^i, I_t^{ij})$, then the collection of $N := N_1 \times N_2$ tuples—where each tuple is a particle-weight pair—is

$$\left\{ \left\{ (z^{i1}, \tilde{w}_t^{i1}), \dots, (z^{iN_2}, \tilde{w}_t^{iN_2}) \right\}_{i \in \{1, \dots, N_1\}} \right\}$$

where for each t and $i = 1, \dots, N_1$, $\sum_{j=1}^{N_2} \tilde{w}_t^{ij} = 1$. After resampling and normalizing, the approximate posterior belief becomes

$$\hat{b}_t(z) = \sum_{k=1}^N w_t^k \delta(z - z^k)$$

which is a form of discrete random measure where the w_t^1, \dots, w_t^N are resampled, normalized weight such that $\sum_{k=1}^N w_t^k = 1$, and $\delta(z - z^k)$ is Dirac-delta function evaluate at z^k . The whole filtering process is depicted in Algorithm 2. Note that as discussed in previous studies [23], our particle filter uses standard re-sampling scheme to ensure the convergence of the mean square error toward zero with a convergence rate of $1/N_2$ for all $q \in \mathcal{Q}$.

VI. NUMERICAL SIMULATIONS

This section presents a suite of numerical simulations to validate both our sensor model and deployment strategy. In particular, we will focus on comparing our approach to popular state-of-the-art approaches under various sensor failure scenarios.

Simulation settings: We consider \mathcal{Q} be a rectangular space $[42.00, 41.51] \times [-73.49, -72.83]$ in \mathbb{R}^2 , some mountain area in Connecticut, U.S.A, where each coordinate corresponds to latitude and longitude, respectively. We let $\mathcal{I} = [-1000, 4000]$ range of elevation in feet, and $r_{\text{eff}} = 2.89$ miles. Targets are uniformly distributed over \mathcal{Q} , and the initial expected value for initial target information over \mathcal{Q} is depicted in Fig. 1. The information vector ranges from -1000 to 4000 , i.e., $\mathcal{I} = [-1000, 4000]$. It is assume that the robots have no prior knowledge of the target information. A number of particles used for the SIR filter is $N = N_1 \times N_2 = 5000 \times 100$. We consider Gaussian kernels for the probability distributions of both the perception model, and the detection

Algorithm 2: Filtering Algorithm

Input: $\hat{b}_{t-1} = \{z^l, w_{t-1}^l\}_{l=1}^N, y_t, \hat{x}_t, I_{\text{range}}$
Output: \hat{b}_t
// SIR Particle Filter
// 1) Update using the observation model
foreach $i \in \{1, \dots, N_1\}$ **do**
 foreach $j \in \{1, \dots, N_2\}$ **do**
 $\tilde{w}_t^{ij} \leftarrow p_{y_{D,t}|q,\hat{x}_t}(y_{D,t} = \mathbf{0} \mid q = q^i, \hat{x}_t)(I_{\text{range}}^{-1} -$
 $w_{t-1}^{ij} f_{y_t|z,\hat{x}_t,y_{D,t}}(y_t = \mathbf{1} \mid z = z_t^{ij}, \hat{x}_t, y_{D,t} \neq$
 $\mathbf{0})) + w_{t-1}^{ij} f_{y_t|z,\hat{x}_t,y_{D,t}}(y_t = \mathbf{1} \mid z, \hat{x}_t, y_{D,t} \neq \mathbf{0})$
// 2) Resample and Normalize
 $\{w_t^l\}_{l=1}^N \leftarrow \text{Resample}(\{\tilde{w}_t^l\}_{l=1}^N, \{w_{t-1}^l\}_{l=1}^N)$
return $\hat{b}_t \leftarrow \{z^l, w_t^l\}_{l=1}^N$
// Low Variance Resampling [24]
function $\text{Resample}(\{\tilde{w}_t^l\}_{l=1}^N, \{w_{t-1}^l\}_{l=1}^N)$
 forall $i \in \{1, \dots, N\}$ **do**
 $\bar{w}_t^i \leftarrow \frac{\tilde{w}_t^i \cdot w_{t-1}^i}{\sum_{i=1}^N \tilde{w}_t^i \cdot w_{t-1}^i}$
 foreach $i \in \{1, \dots, N_1\}$ **do**
 $\delta \leftarrow \text{rand}((0; N_2^{-1}))$
 $\text{cdf} \leftarrow 0, k \leftarrow 0, c_j \leftarrow []$ **for all** j
 for $j = 0, j < N_2$ **do**
 $u \leftarrow \delta + j \cdot N_2^{-1}$
 while $u > \text{cdf}$ **do**
 $k \leftarrow k + 1$
 $\text{cdf} \leftarrow \text{cdf} + \bar{w}_t^{ik}$
 $c_{j+1} \leftarrow k$
 for $j = 1; j \leq N_2$ **do**
 $w_t^{ij} \leftarrow \frac{c_j}{N_2}$
 return $\hat{b}_t = \{z^l, w_t^l\}_{l=1}^N$

TABLE I: Summary of deployment methods considered in current section:

algorithm type:	gradient computation	related studies
non-robust	fully decentralized	[2], [6]
robust ($k = 2$)	decentralized	current paper
max. information gain	centralized	[4]–[8]

model. The value of the equipped noisy sensor's covariance matrix is $\Sigma_I = 0.5\mathbf{I}$, and the binary sensor's covariance is $\Sigma_B = 0.04\mathbf{I}$ where $\mathbf{I} \in \mathbb{R}^{d \times d}$ is an identity matrix. In our simulation, we will compare the three methods summarized in Table I. Note that the three methods presented here are not exactly same as those found from the reference therein, nevertheless, we postulate that the results will be comparable due to the similarities of the ideas.

Convergence of our deployment algorithm: First, the behavior of the deployment strategy is discussed. Given the initial uniform prior belief and an initial configuration at $t = 0$ (upper-left corner), three algorithms, summarized in Table I, were tested. Fig. 2 shows the configurations after $t = 1$ with (a) non-robust method and (b) robust method ($k = 2$). Fig. 3(a) compares the convergence speeds and the cost changes between three methods.

Environmental mapping/filtering performance without sensor failure: Next, we present the evolution of the object map given the uniform, initial map with successive positive

Fig. 1: Elevation map of some region in Connecticut (the ground truth).

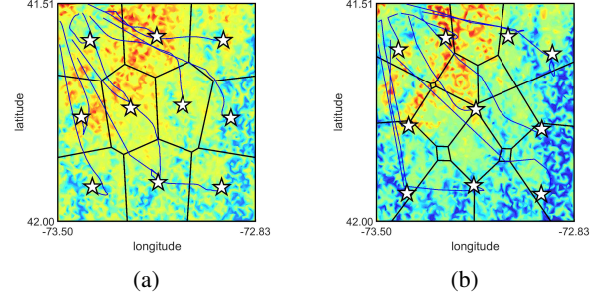

Fig. 2: One-time deployment with non-robust (left) and robust ($k = 2$) (right) overlaid with map at $t = 1$ (lines: gradient descent flow, stars: positions of robots, polygons: partition).

observations, each followed by filtering process and the gradient descent strategy. Fig. 3(b) compares the K-L divergence values between different strategies during the filtering process. While the maximum information gain approach shows the best result, other methods also shows competitive mapping performance relative to the ground truth.

Robustness to sensor failure: We will present a number of examples with sensor failures where robust method become more appealing than non-robust method. The number of sensors that have failed was varied by $\mathcal{F} = \{1\}, \{1, 2\}, \{1, 2, 3\}$. Results for robots configuration and target distributions after 10th step with non-robust and robust methods in the case when $\mathcal{F} = \{1\}$ are shown in Fig. 4. Fig. 5 shows the time evolutions of root-mean-square error (RMSE) between constructed map and the ground truth map for both non-robust method (top) and robust method (bottom) when $\mathcal{F} = \{1, 2, 3\}$. Fig. 6 compares the K-L divergence between difference methods when $|\mathcal{F}|$ was varied between 1

Fig. 3: Convergence test for one-time deployment with different methods.

Fig. 4: The belief at $t = 10$ with non-robust method (left) and robust method (middle), and max. information method (right) Also showing robot configurations (stars, where red stars are robots whose sensors have failed), effective sensing range (dashed line), and partition (solid lines).

and 3. As can be seen from Fig 4–6, the map retrieved by the proposed method $k = 2$ is more robust to the sensor failure compared to that obtained with the non-robust method. In Fig 4, both middle and right, the unmapped area is owe to the limited sensing range.

Statistical results with different initial conditions/faults compositions: Statistical results shows that our method can be used to estimate arbitrary target distribution given randomly chosen initial configuration, with different fault compositions reasonably well. Fig. 7 shows a distribution of K-L divergence values at the $t = 10$ for a given 100 random initial configurations with randomly sampled faults whose numbers are between 1 and 5.

Scalability of our method: We also conducted a series of simulations and have validated that the previous results with 10 robots can be generalize to larger number of robots Fig. 3 shows an example with 100 robots (with 10 sensors failures) where the robust method outperforms the non-robust method.

Remark: It is not surprising to see from the simulation results that the maximum information gain approach has better robustness performance against sensor failures than other methods; however this is due to the presence of central information fusion server, and relatively large communication load. Thus, it is unfair to compare robustness between centralized (max. information gain) and decentralized (non-robust, robust) methods.

VII. CONCLUSIONS AND FUTURE WORK

This paper presents a general deployment strategy for autonomous fleet to maximize the recovery of environmental map over a bounded space, robots to sensor failures. It is expected that our method will fail if there is not enough number of mobile agents having sufficiently long effective sensing ranges compared to the workspace size. One of our future works is, therefore, to employ multi-agent patrolling [25] or sweep coverage [26] algorithms or to resolve such problems where there may not be enough sensors to cover the whole target space. Also, as reported in the literature [15], our combined sensor model has been adopted to emulate the real-world laser scanner’s behavior, nevertheless, it is one of our future works to conduct extensive real world multi-robot experiments for further validation of our range sensor model. Lastly, we assumed in this study that the beliefs are shared between robots such that both tasks of information

gathering, propagating and approximating belief require a central entity. In the future, we will explore how to devise distributed communication protocol to enable distributed belief estimation.
